## Assignment 3

## Non-linear Gauss-Lorentz Curve Fitting

Many types of spectral data consist of several overlapping peaks, each of which has either Gaussian or Lorentzian shape. (Both the Gaussian and the Lorentzian have a single maximum, but the Lorentzian is much longer tailed.) The problem is to determine the location, area, and width of each peak through non-linear least squares inversion. Suppose that we have N data (see Figure 1) with, say,

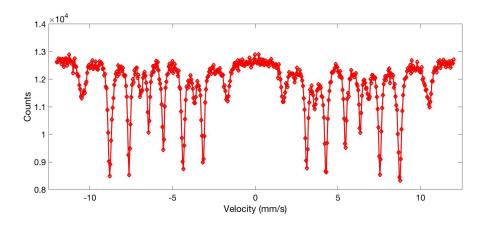

Figure 1: The Mössbauer spectroscopic data to be analyzed in this assignment. For more information about the Mössbauer method, see, e.g., https://en.wikipedia.org/wiki/Mossbauer\_spectroscopy. Note that the spectral "peaks" are pointing downwards! Data courtesy of NASA and the University of Mainz.

q peaks, each characterized by 3 unknown parameters: its center frequency  $f_i$ , area  $A_i$ , and width  $c_i$ . There are then M=3q unknown model parameters  $m=[A_1,f_1,c_1,...,A_q,f_q,c_q]^T$ . The forward relation is nonlinear and of the form  $\mathbf{d}=\mathbf{g}(\mathbf{m})$ . The data uncertainties are approximately Gaussian with standard deviation  $\sigma=0.03\cdot 10^4$  (counts).

In the Gaussian case we have:

$$d_i = \sum_{j=1}^{q} \frac{A_j}{(2\pi)^{1/2} c_j} \exp\left[-\frac{(z_i - f_j)^2}{2c_j^2}\right]$$

In the Lorentzian case we have:

$$d_{i} = \sum_{j=1}^{q} \frac{A_{j}c_{j}^{2}}{(z_{i} - f_{j})^{2} + c_{j}^{2}}$$

Note that in the case of the Gaussian, the quantity  $c_i^2$  has the interpretation of variance, but in the case of the Lorentzian (which has infinite variance), it does not. The problem will typically be overdetermined, at least if N>M and if the peaks do not overlap completely. The equation is linearized around an initial guess using Taylor's theorem. This linearization involves computing a matrix  $\mathbf{G}_k$  of derivatives (in the k'th iteration) with rows

$$\left[\frac{\partial g_i}{\partial A_1} \ \frac{\partial g_i}{\partial f_1} \ \frac{\partial g_i}{\partial c_1} \dots \frac{\partial g_i}{\partial A_p} \ \frac{\partial g_i}{\partial f_p} \ \frac{\partial g_i}{\partial c_p}\right]$$

In this problem the Gaussian and Lorentzian models are simple enough for the derivatives to be computed analytically.

- 1. Derive analytical formulas for  $\frac{\partial g_i}{\partial A_p}$ ,  $\frac{\partial g_i}{\partial f_p}$ , and  $\frac{\partial g_i}{\partial c_p}$  in the Gaussian case.
- 2. Derive analytical formulas for  $\frac{\partial g_i}{\partial A_p}$ ,  $\frac{\partial g_i}{\partial f_p}$ , and  $\frac{\partial g_i}{\partial c_p}$  in the Lorentzian case.
- 3. Evaluate these derivatives at the trial solution  $\mathbf{m}_0 = \mathbf{m}_{prior}$  which is the initial guess chosen from visual inspection of the data. For both the Gaussian and Lorentzian models, find acceptable estimates of the model parameters using the steepest descent algorithm

$$\mathbf{m}_{k+1} = \mathbf{m}_k - \varepsilon_k \left( \mathbf{C}_M \, \mathbf{G}_k^t \, \mathbf{C}_D^{-1} \left( \mathbf{g}_k - \mathbf{d}_{\mathrm{obs}} \right) + \left( \mathbf{m}_k - \mathbf{m}_{\mathrm{prior}} \right) \right)$$

where  $C_M$  is the model covariance matrix,  $C_D$  is the data covariance matrix, k is the iteration number, and  $\varepsilon_k$  is a small positive number chosen to make the algorithm converge properly. Note, that you will have to make your own choice of  $C_M$  and  $\varepsilon_k$ .

The iterations are terminated when the solution fits the observed data "within their uncertainty".

4. Which one of the model choices (the Gaussian or the Lorentzian) are better able to fit the shape of the curve?

One of the drawbacks to these iterative methods is that if the initial guess is too far off, or  $\varepsilon_k$  is too large, the solution may oscillate wildly or diverge from one iteration to the next. You can avoid this behavior by examining the perturbation on each iteration and, if it is too large, decreasing  $\varepsilon_k$ . This procedure will prevent the method from wildly "overshooting" the true minimum but will also slow the convergence.
